

Muskegon Futures: Mega Model Forecasting

Muskegon Watershed Research Partnership

Volume One

Overview: The Muskegon Watershed Research Partnership

In June of 2000, approximately 50 researchers in the field of ecosystem analysis and watershed management met with nearly 50 stakeholders, members of philanthropic organizations, and government officials and over a four day period participated in a workshop specifically convened to consider the current health and future sustainability of the Muskegon River Watershed. During this time, the attendees literally laid out on the table what was currently known about the Muskegon River system, identified gaps in this existing database, reported on current problems, and began to speculate about the watershed's future. Following four days of intensive discussion, the first Muskegon River Watershed Research Summit came to a close, and a comprehensive action plan began to emerge. Many of those attending this pivotal meeting came away with specific ideas about how they might contribute to a better understanding of those issues that are, or will soon become, a priority in the Muskegon River Watershed.

Working together, stakeholders and researchers argued, advocated, and by the end of the June 2000 Summit had proposed several new large multi-university research projects. The Muskegon Watershed Research Partnership was born. The Wege Foundation stepped up to support the acquisi-

tion and interpretation of land use and cover data throughout the watershed; the first comprehensive analysis of its type since 1978. The Great Lakes Fishery Trust supported an extensive study characterizing ecosystems and fishery habitats through the lower portion of the watershed. And, the GLFT funded the most comprehensive assessment of a watershed in this State's history. The Michigan Great Lakes Protection Fund helped fund a study of the relationship between high quality environments and economic vitality. Data depositories were created, an information/education program was implemented, and a book was written (Jeff Alexander's "The Muskegon River: the majesty and the tragedy of Michigan's rarest river", 2006) as a way to convey what was happening and to stir up interest in protecting the Muskegon River's future.

Today the MWRP continues as an interacting group of scientists, representatives of various watershed and environmental organizations, and a patchwork of current and former funders who have invested in the Muskegon River's future. A much strengthened Muskegon Watershed Assembly now plays a central role in facilitating these interactions and promoting an integrated approach to the Muskegon River's sustainability.

The Muskegon River Watershed

At 212 miles long, the Muskegon River is the second longest river in Michigan. The drainage basin encompasses 6,086.5 km² and contains 123 Minor Civil Divisions (MCD). The Muskegon River Watershed is slightly smaller than the entire state of Delaware. Head waters include Higgins and Houghton Lakes, from which the river flows southwest eventually becoming Muskegon Lake, which in turn drains into Lake Michigan via a one mile long channel. The river drops a total of 575 feet from its headwaters to Lake Michigan and has approximately 94 tributaries that flow into it. The Indian name "Muskegon" refers to the lower rivers' extensive riparian wetlands... "the river of grasses"

Overview: What is the Muskegon “Mega Model”?

From the beginning most scientists agreed that it just was not going to be possible to actually measure everything needed to address the problems we already knew something about, much less new issues that would undoubtedly come up during the course of investigation. Also, many of those involved felt it was important to boil down the current science and share what we were learning about the how the Muskegon River Watershed really worked, in a way that would be useful to the various leaders and stakeholders who ultimately help make local and regional decisions. Furthermore, everyone was in agreement that it is easier to prevent problems than it is to try and fix them later, especially when those problems involve water pollution, ecosystem degradation, and habitat destruction. So, the idea that of building a summary ecosystem model to make ecological forecasts of the consequences of alternate management choices arose early and naturally at that Summit. In discussion then it was referred to as the “Mega Model” that would be used to integrate and interpret existing and newly planned investigations, and to vet potential strategies for ensuring the river’s future. Eventually, the model was formally named the **Muskegon River Ecological Modeling System (MREMS)**, but the original name, Mega Model, is one that everyone remembers. Principle science partners originally involved in the creation of the Mega Model Project included the University of Michigan, Michigan State University, Grand Valley State University, and MDNR’s Institute for Fisheries Research. This partnership has since expanded to include researchers at Purdue University, at SUNY-Brockport, and NOAA’s GLERL. Goals for the MegaModel

project, as originally conceived in its’ proposal for funding to the Great Lakes Fisheries Trust (GLFT) included:

- 1: Development of a new integrated model that can serve as the basis of discussion, hypothesis testing, and further research development;
- 2: A formal risk assessment that examines relative severity of important problems facing the watershed such as urban sprawl, sedimentation, and impoundment;
- 3: A linkage of process-based models with empirical data sets and ecological service assessment, and;
- 4: A number of public-oriented tools and modeling products.

Almost eight years later, there have been numerous spin-off studies initiated and completed, many journal articles, book chapters, theses, and dissertations published.

However, the MWRP public information bulletin series “Muskegon Futures:”, of which this is the first installment, really best represents our attempt to meet the **goals** and spirit of the “MegaModel” project. Through these brief publications the project investigators hope to provide useful summary information that links results of technical science focused on a wide variety of topics to the practical and very real issues of sustainability that the Muskegon face’s in its’ not too **distant** future.

Stakeholder Organizations

A requirement that the GLFT placed on all of the special Muskegon River proposals it entertained, was that it be the joint proposal of both University scientists, and regional stakeholders who represented the interests of the all those who depend on the Muskegon River’s future: the people who live, work, or play in it’s watershed. Participating in the development of the original Mega Model proposal, and in subsequent stakeholder conference meetings in 2002, 2003, 2004 and 2007 were representatives of the following organizations:

**The Muskegon Watershed Assembly,
Michigan Dept of Natural Resources,
Michigan Dept of Environmental Quality,
Consumers Energy,
Trout Unlimited,
Brooks Township,
The Land Conservancy of West Michigan,
Timberland RC&D,
The Lake Michigan Federation,
The Michigan Lakes & Streams Association,
Brooks Township**

Watershed Stakeholders Set the Ecosystem Modeling Agenda

Scientists enjoy building models because... that's just what scientists do. But what kind of models? Designed to answer what kind of questions? The role of the Stakeholder groups in the Mega Model project was to specify which questions the science team should be trying to answer about the future of the Muskegon. In June 2002, representative of 13 watershed and environmental organizations met at GVSU's Annis Water Resources Center in Muskegon with project investigators to chart

out a direction for the modeling project by settling on specific questions and resource management issues towards which model building and calibration could be aimed. Weighing both the nature of practical concerns they had regarding watershed's future sustainability, and descriptions by the project scientists of what was realistically achievable and what was not, the group settled on 3 major areas of focus:

1. Landuse Management
2. Erosion Management
3. Dam and Hydrologic Management

Building on the framework the group labored together to propose a series of explicit scenarios (imaginable future management actions or policies) which could be evaluated with the developing MEMS system. Given a target of t3-4 scenarios per area of focus, we walked away at the end of that long day with 37 management scenario to evaluate.

Intervening discussions, new information, and plain lack of resources has whittled the list down to an essential 19 scenarios that have been completed to date. These include:

- 4 major land use scenarios representing different strategies and commitments to urban development, forest growth, and agricultural preservation.
- 3 different riparian buffer (set-back regulation) scenarios applied to each of the baseline urbanization scenarios (total of 6)
- A series of 11 historical and back casting scenarios to estimate river condition and function from 1830 to 1998
- 1 main stem dam removal scenario
- Researchers themselves have added a climate change scenario which is in the process of being completed.

“From 1978 to 1998 there was a net loss of 561.4 km² of Farmland in the Muskegon River Watershed.”

Can you trust a computer model?

Some people distrust all computer based modeling, other people take every prediction to be hard scientific fact. What are ecological forecasting systems like MREMS good for? How right or how wrong can they be?

MWRP scientists have done their best to carefully test and validate the model components of MREMS. And by all objective standards these models accurately reproduce current conditions given current inputs. But of course no one can validate model predictions about the future without a time machine. It is important, therefore, not to take any specific prediction of these models too seriously. But, it is equally important not to summarily dismiss them. Computer model forecasts of complex real world systems like rivers, are bound to be wrong in many of their specific details. The goal of modeling for ecosystem management is not perfect and detailed prediction. Instead the goal is to systematically gather together what is known about how the an ecosystem “works”, and then construct a useful simplification for discussion and further testing. Scientists, by building models based on the best available scientific theory and relevant data hope their models will mimic the essential behavior of the system they represent. If a model faithfully represents fundamental processes, we can study the way it responds to various changes and perturbations (management scenarios in our case) and hope to infer something about the way the real system will behave. Testing a small model of a new airplane in a wind tunnel provides a useful indication of how the design will fly when built. But it isn't a substitute for eventually flying the real plane with a test pilot. Models never really prove anything about the future (or the past for that matter). They only suggest. But given the many challenges facing the Muskegon watershed, we need suggestions now in order to rationally plan for the future.

How the Mega Model works

The Muskegon River Ecological Simulation System (a.k.a. the Mega Model) is **technically best** described as a “multi-model”. That is, it is really a large set of independent models **that** treat various aspects of the Muskegon River ecosystem, but which are synchronized by shared inputs **from climate**, land cover, and river network **models**. Geo-referenced data exchange protocols help models operating at different spatial and time scales to communicate and integrate outputs. For a typical biological prediction, output from 5-10 different models executed by working groups at different universities are integrated to produce a single prediction. For example to evaluate the effect of a Farmland preservation scenario on the growth rate of young Steelhead, output from the following sequence of model runs is required:

- (1) Land Transformation Model (LTM2) at Purdue to produce the land cover pattern;
- (2) our Standard Climate Model (at MSU) to provide detailed rain, temperature, and radiation **inputs**;
- (3) a **distributed landscape hydrology model (ILHM) developed at MSU to redistribute precipitation and snowmelt into evapotranspiration, groundwater recharge, and overland flow based on climate inputs.**
- (4) a groundwater model (MODFLOW) at MSU to **simulate the flow of water once it becomes recharge until it discharges to surface water bodies**;
- (5) a surface water routing model (HEC-HMS) at UM which uses
- (6) a custom synthetic unit hydrograph model and standard channel routing routines to move water through the river channels systems;
- (7) a temperature model (SRTM+) at UM to predict longitudinal and seasonal changes in water temperature;
- (8) a reach scale hydraulic model (HEC-RAS) at UM to predict daily changes in depth and velocity distributions;
- (9) a spatial habitat and benthic biomass model developed by UM to describe substrate and food availability; **and finally**
- (10) an Individual based bioenergetic model for steelhead (SHMUSK) run by Fisheries Projections in Connecticut.

MREMS model executions are, like the whole project, a very collaborative effort!
